## Why this study was needed

Mountain summits are popular destinations for recreationists visiting national parks and other protected areas. However, increasing use in high alpine environments can change both the ecological and social conditions there, including damaging fragile alpine soils and vegetation or increasing feelings of crowding in remote areas. Safety concerns also arise when terrain features cause bottlenecks and visitor queuing.

Park and protected area managers need reliable estimates of visitor use in alpine areas and mountain summits to effectively monitor and understand impacts to ecosystems, visitor experiences, and safety. Typically, they rely on observational methods such as automated trail counters to monitor visitation. However, collecting visitor use data in the harsh climates and exposed, rocky terrain of remote alpine mountain summits is quite challenging.

This study used camera traps to collect visitor use data along the Keyhole Route near the summit of Longs Peak in Rocky Mountain National Park, Colorado, to determine if counts from near the trailhead could accurately estimate use at the summit. This method could provide a framework for using data from a lower elevation, easily accessible area to estimate visitor use in remote, high-elevation locations.

## How it was done

The researchers chose the Keyhole Route to the summit of Longs Peak to test their methodology. From its trailhead, the Longs Peak trail accesses Chasm Lake and Estes Cone in addition to the peak. The Keyhole Route is the only route to the summit of Longs Peak that does not require ropes or climbing equipment. In summer months, the peak, the only site above 14,000 feet within Rocky Mountain National Park, receives heavy use. Park managers have used automated trail counters at the Longs Peak trailhead since 2011 to monitor how many visitors use the trail and when. However, due to the high elevation and challenging terrain, visitor use monitoring beyond this point had not been conducted previously.

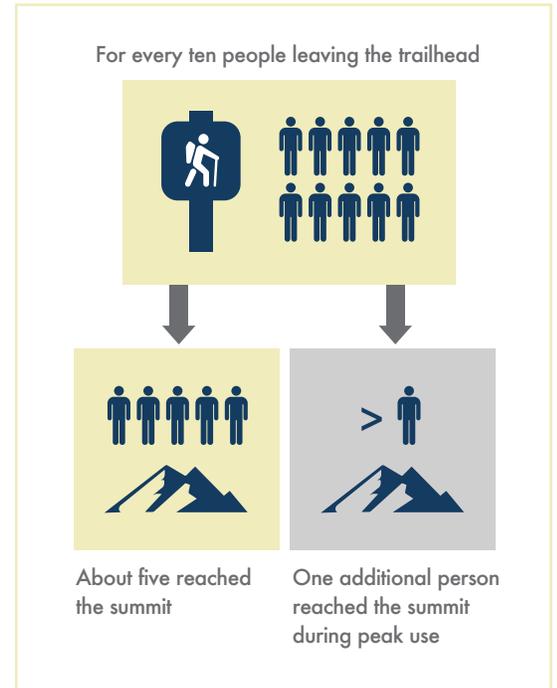

In three weeks during July and August of 2015, corresponding to both high visitor use and ideal weather, the researchers placed two automated cameras along the Keyhole Route. Research technicians then used the images to count ascending and descending visitors in one-hour segments. They then compared that information to data collected by automated counters near the trailhead. The researchers conducted regression analyses to determine whether statistical relationships existed between the counter data from the trailhead and the camera data from near the summit.

# What the researchers discovered

For Longs Peak, the researchers determined that the highest use at the trailhead (about 650 people in one day) corresponded to about 60 people near the summit in a one-hour stretch. Most often the hour of maximum use was between 8:00 a.m. and 9:00 a.m.

Importantly, counts from the trailhead predicted visitor use near the summit. For the Longs Peak Trail, ten additional people leaving the trailhead translated to about five reaching the summit on a given day and just more than one additional person on the summit during the hour of maximum use.

In addition, for every ten extra people who reached the summit on a given day, the number of people on the summit during the hour of maximum use increased by a little less than three on average. These relationships were statistically significant, meaning that visitor counts collected at the Longs Peak trailhead can accurately and reliably estimate levels of visitor use in more rugged, difficult to access, and remote stretches of the Keyhole Route near the summit of Longs Peak.

# Why it's important

Park and protected area managers need information about visitor use on mountain summits to sustainably manage recreation in these areas. Knowing when the hour of peak visitation occurs can help schedule ranger patrols to increase contact with visitors and evaluate conditions during periods of high use. Collecting data in remote areas with rugged terrain can be costly in terms of equipment expenses as well as staff time. This research provides managers with an analysis technique (discussed in detail in the paper) they can use to accurately estimate visitor use in remote or rugged locations based on data collected from trailheads.
